Actor-Critic Reinforcement Learning with Energy-Based Policies

Nicolas Heess

Yee Whye Teh

Abstract

We consider reinforcement learning in Markov decision processes with high dimensional state and action spaces. We parametrize policies using energy-based models (particularly restricted Boltzmann machines), and train them using policy gradient learning. Our approach builds upon Sallans and Hinton (2004), who parameterized value functions using energy-based models, trained using a non-linear variant of temporal-difference (TD) learning. Unfortunately, non-linear TD is known to diverge in theory and practice. We introduce the first sound and efficient algorithm for training energy-based policies, based on an actor-critic architecture. Our algorithm is computationally efficient, converges close to a local optimum, and outperforms Sallans and Hinton (2004) in several high dimensional domains.

1. Introduction

A major challenge in reinforcement learning is to find successful policies in problems with high-dimensional state or action spaces. In order to solve these problems effectively, it is advantageous to learn representations of the state and action spaces that enable a policy to achieve high performance. In this paper, we develop a framework for parameterizing richly structured policies, and for finding those with (locally) optimal performance.

We consider a class of policies based on energy-based models (LeCun et al., 2006), where the (negative) log probability of selecting an action is proportional to an energy function. Energy-based models have been widely studied in both supervised and unsupervised learning. They can learn deep, distributed representations of high-dimensional data (such as images) and model high-order dependencies, and here we will use them to directly parametrize representations over states and actions. We explore in detail a class of energy-based models called restricted Boltzmann machines (RBMs; Freund and Haussler, 1994; Welling et al., 2004). RBMs and conditional RBMs have been applied to a range of challenging tasks including multi-class classification (Larochelle and Bengio, 2008), collaborative filtering (Salakhutdinov et al., 2007), motion capture modeling (Taylor and Hinton, 2009), modeling of transformations in natural images (Memisevic and Hinton, 2010), and structured output prediction (Mnih et al., 2011).

To successfully use energy-based policies for reinforcement learning, it is necessary to address several challenges. First, the parameterized representations can be highly non-linear, leading to non-convex objectives with multiple optima. Second, it is often intractable to compute the partition function that normalizes the energy function into a probability distribution. Third, evaluating a policy typically has high variance, since the performance...
depends on the rewards accumulated over a complete trajectory. Prior work (Sallans, 2002; Sallans and Hinton, 2004; Otsuka et al., 2010; Elfving et al., 2010) partially addressed these issues using value-based reinforcement learning. The idea was to approximate the action-value function by the free energy of an energy-based model, and to train it by temporal-difference (TD) learning. However, this approach has a serious drawback: TD learning is known to diverge, both in theory and in practice, when using non-linear value functions (Tsitsiklis and Van Roy, 1997). In addition, the policy is based on an arbitrary temperature which makes the algorithm hard to tune in practice.

We introduce a new approach to reinforcement learning with energy-based policies. The basic idea is to adjust the policy parameters to follow the gradient of the policy performance, using sample trajectories to obtain estimates of the gradient (Williams, 1992; Sutton et al., 1999; Baxter and Bartlett, 2001). One major advantage of this approach is that it converges to a local optimum, even for non-linear policies. Simple policy gradient methods are sensitive to the parameterization of the policy, and also suffer from high variance in the gradient estimates. We address these shortcomings by following the natural gradient, which reduces the dependence of the performance of the policy gradient on the parameterization (Kakade, 2001); and by using an actor-critic architecture, which uses an approximate value function to reduce the variance in the gradient estimates (Peters and Schaal, 2008; Bhatnagar et al., 2009). We introduce two novel natural actor-critic algorithms for efficiently following the gradient of energy-based policies without resorting to explicit computation of the partition function. We apply our algorithms to learn RBM policies in a number of tasks, finding that they converge quickly to reasonable solutions in all tasks and consistently outperform Sallans and Hinton (2004), which sometimes even fails to converge.

2. Energy-based policies

We consider stationary Markov decision processes (MDPs) with bounded rewards and high dimensional state and action spaces denoted $S$ and $A$ respectively. Denote the state, action and reward at time $t$ by $s_t$, $a_t$ and $r_t$ respectively, and the state transition probabilities and expected reward function by $P(s_{t+1}|s_t, a_t)$ and $R(s_t, a_t)$. We will consider stochastic and stationary polices described by conditional distributions over actions $\pi^\theta(a; s)$ parameterized by $\theta$. We assume that given policy $\pi^\theta$ the MDP is ergodic with stationary distribution $d^\theta$.

In this paper we consider energy-based policies which can be expressed as conditional joint distributions over actions $a$ and a set of latent variables $h$:

$$\pi^\theta(a, h; s) = \frac{1}{Z(s)} e^{\phi(s, a, h)^\top \theta}$$

(1)

where $\phi(s, a, h)$ are a pre-defined set of features and $Z(s) = \sum_{a, h} \exp(\phi(s, a, h)^\top \theta)$ is the normalizing partition function. The policy itself is then obtained by marginalizing out $h$. The latent variables allow energy-based policies to parametrize complex non-linear and non-factorial relationships between actions and states, even though the underlying parameterization (1) is log linear in the features $\phi(s, a, h)$. For example, in a conditional restricted Boltzmann machine (RBM), the states $s$, actions $a$ and latent variables $h$ are all high-dimensional binary vectors, and (1) is parameterized as:

$$\pi^\theta(a, h; s) = \frac{1}{Z(s)} e^{s^\top W_s h + a^\top W_a h + b_s^\top s + b_a^\top a}$$

(2)
where the parameters are matrices $W_s, W_a$ and vectors $b_s, b_a, b_h$ of appropriate dimensionalities. Marginalizing out $h$, we get a non-linearly parameterized policy:

$$F^\theta(s, a) = -b_s^T s - b_a^T a - \sum_i \log(1 + e^{s^T W_{si} + a^T W_{ai} + b_{si}}), \quad \pi^\theta(a; s) = \frac{1}{Z(s)} e^{-F(s, a; \theta)}$$ (3)

where $i$ indices the latent variables, and $W_{si}, W_{ai}, b_{si}$ are parameters associated with latent variable $h_i$. The quantity $F(s, a; \theta)$ is called the free energy.

### 2.1. Free-energy Sarsa

**Sallans and Hinton (2004)** use the RBM free energy as a non-linear function approximator. Specifically, they approximate the action-value function $Q^\theta(s, a)$ of a discounted MDP using $-F^\theta(s, a)$, and select actions according to a Boltzmann exploration policy,

$$\pi^\theta(a; s, T) = \frac{1}{Z(s, T)} e^{-F(s, a; \theta)/T}$$ (4)

where the temperature $T$ scales units of reward into units of probability: as $T \to \infty$ the policy becomes uniform; as $T \to 0$ it becomes greedy. The parameters of the RBM are updated using a non-linear version of the Sarsa algorithm, with time-varying step size $\beta_t$,

$$\delta_t = r_{t+1} - \gamma F^\theta_{t+1}(s_{t+1}, a_{t+1}) + F^\theta_{t}(s_t, a_t)$$

$$\theta_{t+1} = \theta_t - \beta_t \delta_t \nabla_{\theta} F^\theta_{t}(s_t, a_t),$$ (5)

where $\delta_t$ is the TD error and $\gamma$ is the discount factor of the MDP. We refer to this algorithm as energy-based Sarsa (ESARSA). Since Sarsa is a control algorithm based on TD learning, it may diverge with non-linear function approximations (**Tsitsiklis and Van Roy, 1997**). Recently, convergent non-linear prediction algorithms based on gradient TD have been developed, however even these may still diverge when used for control (**Maei et al., 2009**).

### 2.2. Policy gradient

In this paper we consider an average reward formulation of MDPs. Our objective is to find parameters $\theta$ that (locally) maximize the average reward per time-step $J(\theta)$,

$$J(\theta) = \lim_{T \to \infty} \frac{1}{T} \mathbb{E}^\theta \left[ \sum_{t=1}^{T} r_t \right] = \mathbb{E}_{\pi^\theta} [R(s, a)]$$ (6)

where $\mathbb{E}^\theta$ denotes expectation under $\pi^\theta$ and $\mathbb{E}_{\pi^\theta}$ denotes expectation under the stationary distribution (where $s \sim d^\theta$ and $a|s \sim \pi^\theta(\cdot; s)$). The state-value function $V^\theta(s)$ and action-value function $Q^\theta(s, a)$ for policy $\pi^\theta$ are given by the differential reward from $s$ (and $a$),

$$Q^\theta(s, a) = \sum_{t=1}^\infty \mathbb{E}^\theta [r_t - J(\theta)|s_0 = s, a_0 = a]$$ (7)

$$V^\theta(s) = \sum_{t=1}^\infty \mathbb{E}^\theta [r_t - J(\theta)|s_0 = s] = \sum_{a \in \mathcal{A}} \pi^\theta(\cdot; a)Q^\theta(s, a) = \mathbb{E}_a[Q^\theta(s, a)]$$ (8)

where $\mathbb{E}_a$ denotes expectation under $a|s \sim \pi^\theta(\cdot; s)$. The advantage function is the differential value for action $a$ in state $s$:

$$A^\theta(s, a) = Q^\theta(s, a) - V^\theta(s)$$ (9)
Policy gradient methods update the policy parameters \( \theta \) to follow the gradient of the average reward. The policy gradient theorem (Baxter and Bartlett, 2001; Sutton et al., 1999; Bhatnagar et al., 2009) provides the gradient of \( J(\theta) \) with respect to \( \theta \),

\[
\nabla_\theta J(\theta) = \mathbb{E}_{sa}^\theta \left[ A^\theta(s,a) \nabla_\theta \log \pi^\theta(a;s) \right]
\]

(10)

In practice, the advantage function \( A^\theta \) is unknown and must be approximated. Actor-critic policy gradient algorithms estimate the advantage function, \( \hat{A}^w \approx A^\theta \), and update this estimate (the critic) in parallel with the policy parameters (the actor). If the parameterization of the approximation \( \hat{A}^w \) is compatible with the parameterization of the policy, then this approximation does not introduce any bias into the gradient direction (Sutton et al., 1999). A parameterization is compatible if it satisfies

\[
\nabla_w \hat{A}^w(s,a) = \nabla_\theta \log \pi^\theta(a;s)
\]

(11)

That is, \( \hat{A}^w(s,a) = \psi^\theta(s,a)^\top w \) where \( \psi^\theta(s,a) = \nabla_\theta \log \pi^\theta(a;s) \). Furthermore, the parameters \( w \) should minimize the mean-squared-error (MSE),

\[
w = \arg\min_w \mathbb{E}^\theta_{sa} \left[ (A^\theta(s,a) - \psi^\theta(s,a)^\top w)^2 \right]
\]

(12)

This can be obtained by stochastic gradient updates:

\[
w_{t+1} = w_t + \alpha_t (\delta_t - \psi^\theta_t(s_t,a_t)^\top w_t) \psi^\theta_t(s_t,a_t)
\]

(13)

where \( \theta_t \) is the current policy parameter, \( \alpha_t \) is a step size and \( \delta_t \) is an unbiased estimate of \( A^\theta(s_t,a_t) \) (later).

The direction of the vanilla policy gradient is sensitive to reparameterizations of the policy that don’t affect the action probabilities. Natural policy gradient algorithms (Kakade, 2001; Peters and Schaal, 2008) remove this dependence, by finding the direction that improves \( J(\theta) \) the most for a fixed small amount of change in distribution (e.g. measured by KL divergence). The natural policy gradient \( \nabla_\theta^{\text{nat}} J(\theta) \) is defined by

\[
\nabla_\theta^{\text{nat}} J(\theta) = G_\theta^{-1} \nabla J(\theta), \quad G_\theta = \mathbb{E}_{sa}^\theta \left[ \nabla \log \pi(s,a) \nabla \log \pi(s,a)^\top \right]
\]

(14)

where \( G_\theta \) is the Fisher information matrix. When using compatible function approximation, we find that,

\[
\nabla_\theta J(\theta) = \mathbb{E}_{sa}^\theta \left[ \nabla_\theta \log \pi^\theta(a;s) A^\theta(s,a) \right] = \mathbb{E}_{sa}^\theta \left[ \nabla_\theta \log \pi^\theta(a;s) (\nabla_\theta \log \pi^\theta(a;s))^\top w \right] = G_\theta w
\]

(15)

and the natural gradient simplifies to \( \nabla_\theta^{\text{nat}} J(\theta) = w \). Policy parameters updates are then:

\[
\theta_{t+1} = \theta_t + \beta_t w_{t+1},
\]

(16)

The final ingredient is estimating the advantage function \( A^\theta(s,a) \). One unbiased estimate is the TD error:

\[
\delta_t = r_{t+1} - J(\theta) + V^\theta(s_{t+1}) - V^\theta(s_t)
\]

(17)
Actor critic learning for energy-based policies

which is used by Bhatnagar et al. (2009) to motivate their natural TD actor-critic (NAT-DAC) algorithm: They approximate the state-value function, and hence the TD error, using a linear function approximator $\hat{V}_\theta(s) \approx f(s)^T \mathbf{v}$, where $f(s)$ is a state-dependent feature vector and $\mathbf{v}$ are updated by TD learning:

$$\hat{J}_{t+1} = (1 - \zeta_t)\hat{J}_t + \zeta_t r_{t+1}$$

$$\delta_t = r_{t+1} - \hat{J}_{t+1} + f(s_{t+1})^T \mathbf{v}_t - f(s_t)^T \mathbf{v}_t$$

$$\mathbf{v}_{t+1} = \mathbf{v}_t + \alpha_t \delta_t f(s_t)$$

Provided that the average reward, TD error and critic are updated on a slower time scale than for the actor, and step sizes are reduced at appropriate rates, NATDAC converges to a policy achieving near-local maximum average reward (Bhatnagar et al., 2009, Section 5).

3. NATDAC for energy-based policies

Energy-based policies pose a challenge to policy gradient methods. Both vanilla policy gradient updates and natural actor-critic updates require the computation of compatible features $\psi^\theta(s, a) = \nabla_\theta \log \pi^\theta(s, a)$. For an energy-based policy, this requires the computation of two expectations:

$$\psi^\theta(s, a) = \nabla_\theta \log \pi^\theta(s; a) = \nabla_\theta \log \sum_h e^{\phi^\theta(s, a, h)^T \theta} - \nabla_\theta \log Z(s)$$

$$= E^\theta_h [\phi(s, a, h)] - E^\theta_{ah} [\phi(s, a', h)] \overset{def}{=} \phi^\theta(s, a) - E^\theta_{a'} \left[ \phi^\theta(s, a') \right].$$

where $E^\theta_h$ is the expectation wrt the conditional of $h$ given $a$ and $s$ while $E^\theta_{ah}$ is wrt both $a$ and $h$. The first expectation, which we denote by $\phi^\theta(s, a)$, can be computed efficiently in a wide class of energy-based models, including RBMs. The second expectation involves a sum over all actions, and is intractable to compute in high-dimensional action spaces.

We now propose two incremental actor critic algorithms that avoid evaluating either this expectation or the partition function. The first algorithm energy-based NATDAC (ENATDAC) uses independent samples from the energy-based policy to approximate the intractable expectations. The second algorithm, energy-based Q-value natural actor critic (EQNAC) uses a deterministic approximation and has a lower computational requirement.

3.1. Energy-based NATDAC

For our first algorithm, we note that energy-based policies such as RBMs may be efficiently sampled, for example by blocked Gibbs sampling, without explicitly computing the partition function. Unbiased estimates of the update (13) can then be formed using two independent unbiased estimates of the compatible features $\psi^\theta(s, a)$,

$$\hat{\psi}_t' = \phi^\theta_t(s_t, a_t) - \frac{1}{K} \sum_{k=1}^K \phi^\theta_t(s_t, a'_k), \quad \hat{\psi}_t'' = \phi^\theta_t(s_t, a_t) - \frac{1}{L} \sum_{l=1}^L \phi^\theta_t(s_t, a''_l)$$

$$\mathbf{w}_{t+1} = \mathbf{w}_t + \alpha_t \left( \delta_t - \hat{\psi}_t' \mathbf{w}_t \right) \hat{\psi}_t''$$

(20)
where $a'_k, a''_l \sim \pi^{\theta_t}(\cdot; s)$ iid. Because (20) is equal in expectation to the critic update (13), the two time scale convergence proof for NATDAC (Bhatnagar et al., 2009, section 5.3) can be applied. Specifically, under our assumption that the critic is updated on a much slower time-scale than the actor, the policy $\theta_t$ and therefore $\phi^{\theta_t}$ is effectively stationary during critic updates. As a result, the TD learning updates (20) are based on a function approximator that is linear in $\phi^{\theta_t}$, and do not suffer from the divergence issues faced by energy-based Sarsa.

One drawback of the NATDAC algorithm is that the quality of the state-value function approximator depends on the feature vector $f(s)$. Although the algorithm converges, the quality of the final policy may be significantly affected by the choice of features. In an energy-based framework, it is possible to marginalize over $\phi^{\theta}(s, a)$ to define an energy-based feature vector $f(s) = E^\theta_\phi[\phi^{\theta}(s, a)]$. Again, this expectation is intractable to compute, but can be approximated by a third set of samples from the policy, $a''_m \sim \pi^\theta(s, \cdot)$

$$f_t = \frac{1}{M} \sum_{m=1}^M \phi^{\theta_t}(s_t, a''_m)$$

(21)

Pseudocode for energy-based NATDAC is given in Algorithm 1. In summary, it uses an advantage actor-critic, based on TD learning with an energy-based feature vector, and using the sample approximation to the intractable expectations, and updates the policy by following the natural gradient.

### 3.2. Energy-based Q-value natural actor-critic

We now introduce our second algorithm, EQNAC, which is also based on a natural actor-critic approach. The key new idea is to note that, when using the compatible function approximator $\psi^{\theta}(s, a)$, the approximate advantage function $\hat{A}^w(s, a)$ can be represented in terms of an approximate action-value $\hat{Q}^w(s, a)$,

$$\hat{A}^w(s, a) = \psi^{\theta}(s, a)\top w = \left(\phi^{\theta}(s, a) - E^\theta_{a'} \left[ \phi^{\theta}(s, a') \right] \right)\top w = \phi^{\theta}(s, a)\top w - E^\theta_{a'} \left[ \phi^{\theta}(s, a') \right]\top w$$

$$\hat{Q}^w(s, a) = \phi^{\theta}(s, a)\top w$$

(22)

This suggests that it is sufficient to estimate the action-value function $Q^\theta(s, a)$ by a linear approximator $\hat{Q}^w = \phi^{\theta}(s, a)\top w$. This representation does not involve any intractable expectations. The EQNAC algorithm updates the critic parameters $w$ by TD learning, and updates the policy parameters $\theta$ by following the natural gradient in the direction of $w$. Pseudocode for EQNAC is shown in Algorithm 2. Again, for an effectively stationary policy the TD learning procedure is linear in $\phi^{\theta}$ and therefore avoids the divergence issues.
encountered by energy-based Sarsa. Unlike ENATDAC, this algorithm does not require repeated sampling of actions to estimate the expectations. Furthermore, it only maintains two sets of parameters $\theta$ and $w$, and does not require a state feature vector to be defined.

4. Experiments

We evaluate our two algorithms, comparing them against ESARSA on three tasks below. As an additional comparison, we also considered a neural network (NN) with stochastic policy task formulation. For ESARSA on the blocker and octopus arm tasks, algorithms use an average reward formulation; whereas ESARSA uses a discounted reward. We use exact sampling for all algorithms in the stochastic policy task ($\pi = \text{uniform}$) is an example where a stochastic policy is required to deal with state aliasing, and serves to demonstrate that RBMs can model stochastic policies with high-dimensional action spaces. The action space consists of $N$ binary variables and there are $K$ unobserved states. Each of the unobserved states is associated with one particular configuration of the action variables. If the environment is in state $k$ and the associated action is performed a reward of 10 is received and the environment transitions into state $k + 1$ (or into state $1$ from $K$). Otherwise the state is unchanged and no reward is provided. Since the agent does not observe the environment state the optimal policy is to choose the $K$ “good” action configurations with equal probability, achieving an average reward of $\frac{10}{K}$. A deterministic policy will get zero reward since it will get stuck in one of the states. Further, it is necessary to model dependencies between action variables: for independently drawn action variables the probability of generating a “good” configuration is $\frac{1}{K}$.

The stochastic policy task (Sallans, 2002) is an example where a stochastic policy is required to deal with state aliasing, and serves to demonstrate that RBMs can model stochastic policies with high-dimensional action spaces. The action space consists of $N$ binary variables and there are $K$ unobserved states. Each of the unobserved states is associated with one particular configuration of the action variables. If the environment is in state $k$ and the associated action is performed a reward of 10 is received and the environment transitions into state $k + 1$ (or into state $1$ from $K$). Otherwise the state is unchanged and no reward is provided. Since the agent does not observe the environment state the optimal policy is to choose the $K$ “good” action configurations with equal probability, achieving an average reward of $\frac{10}{K}$. A deterministic policy will get zero reward since it will get stuck in one of the states. Further, it is necessary to model dependencies between action variables: for independently drawn action variables the probability of generating a “good” configuration is $\frac{1}{K}$.

1. For ESARSA we consider initial learning rate, speed of decay of the learning rate, decay of the exploration temperature $T$ (starting at 1), and variance of the Gaussian distribution used to randomly initialize the policy parameters at the beginning of learning. For the policy gradient algorithms we consider $\alpha_0$, $\beta_0$, rate of decay for $\alpha$, $\beta$, and scale of random initialization. We use $\zeta = \alpha$ in all experiments.

2. 500 actions for stochastic policy; 1000 epochs for blocker task; 100 epochs for octopus arm.

Algorithm 2 EQNAC

1: Input: $J_0, w_0, \theta_0, s_0$
2: $a_0 \sim \pi^0(\cdot; s_0)$
3: for $t = 0, 1, 2, \ldots$ do
4:   $r_{t+1} = R(s_t, a_t)$
5:   $s_{t+1} \sim P(\cdot|s_t, a_t)$
6:   $a_{t+1} \sim \pi^0(\cdot; s_t)$
7:   $J_{t+1} = (1 - \zeta_t)J_t + \zeta_t r_{t+1}$
8:   $\delta_t = r_{t+1} - J_{t+1} + \phi^\theta_t(s_{t+1}, a_{t+1})^T w_t - \phi^\theta_t(s_t, a_t)^T w_t$
9:   $w_{t+1} = w_t + \alpha_t \delta_t \phi^\theta_t(s_t, a_t)$
10: $\theta_{t+1} = \theta_t + \beta_t w_{t+1}$

Figure 1: Stochastic policy task: The table shows the task-parameters for the three versions of the task. Results are shown for ENATDAC (green), EQNAC (blue), SARSA (red), and NN (magenta). The black line shows average reward for the optimal policy. The light gray line shows the reward with independent actions.

Figure 2: Blocker task: The top plot illustrates several steps in a blocker game (adapted from Sallans and Hinton 2004). To win, the agents need to cooperate. Here, agents 1, 2 force the blockers to split so that agent 3 can enter the end zone in the middle. The bottom plot shows, for each algorithm, mean and standard deviation of the average reward per step of the learned policies for 20 restarts with different random initializations (see Fig. 5, 6 in the supplemental material for individual traces).

is very low. We consider three versions of the task with \( N = 5, 6, 8 \), and \( K = 2, 3, 3 \) (cf. Fig. 1). The first version was considered in Sallans (2002). We used an RBM with 1 hidden unit for task 1 and 2 hidden units for tasks 2 and 3. Training was performed for 20000 actions. Results are shown in Fig. 1. The NN models each action dimension independently and therefore performs very poorly (see supplemental material for further discussion). In contrast, the RBM learns to represent these correlations via stochastic latent variables and performs very effectively. When training the RBM, ESARSA is only able to find the optimal policy for task 1, whereas EQNAC and ENATDAC find optimal policies in all cases.³

The blocker task (Sallans 2002; Sallans and Hinton 2004) is a multi-agent task in which agents have to reach the end zone at the top of a playing field while blockers try to stop them. In each iteration of the game, each agent moves by one step in one of four directions, while the blockers behave in a deterministic manner, moving left or right to block the agents. We used a 7 × 4 board with 3 agents and 2 blockers as illustrated in Fig. 2. Blockers have a limited range of responsibility, with blocker 1 responsible for columns 1-4 and blocker 2 for columns 4-7. The state space consists of locations for each agent and for blocker (using 1-of-N encoding for each). A game is started by randomly placing agents at the bottom and the blockers at the top. It is played for 40 steps or until one of the agents reaches the end zone. A reward of -1 is given for each step prior to reaching the end zone, and a reward of 1 when one of the agents succeeds and the game is ended. We used RBMs

³. Although only the first 20000 actions are shown we allowed 50000 actions for ESARSA training. For task 2 additional training leads to a small improvement relative to the performance after 20000 actions but not for task 3 (see also Fig. 1 in supplemental material).
Actor critic learning for energy-based policies

Figure 3: Octopus arm: Average number of steps required to hit the target. For each algorithm mean and std.-dev. for 10 restarts with different random initializations are shown. Fig. 3 in the suppl. material shows individual traces.

with 16 hidden units, and learning was performed for 400000 actions. Results are shown in Fig. 2. EQNAC and ENATDAC consistently achieved good results. ESARSA and NN generally converged more slowly and found lower quality policies.

In this task we also experimented with several different state feature vectors $f(s)$, as required by ENATDAC (but not the other algorithms). We tested: randomly generated binary features (as e.g. Bhatnagar et al., 2009), choosing the dimensionality $D$ of $f(s)$ to be lower than the number of states (which is 87808; we experimented with $D = 400, 1000$); raw feature encoding based on the state vector $s$ directly; and the “energy based” feature vector described in section 3.1. We found that a poor choice of $f(s)$ can significantly reduce the asymptotic performance. The energy-based features performed very well, only equalled by large sets of carefully scaled random features.

Finally, we tested our algorithms on an octopus arm (Engel et al., 2005) task. The aim is to learn to control a simulated octopus arm to hit a target. The arm consists of $C$ compartments and is attached to a rotating base. There are $8C + 2$ continuous state variables ($x,y$ position/velocity of the nodes along the upper/lower side of the arm; angular position/velocity of the base) and $3C + 2$ action variables that control three muscles (dorsal, transversal, central) in each compartment as well as the clockwise and counter-clockwise rotation of the base. Previous work (Engel et al., 2005) simplified the high-dimensional action space using 6 “macro-actions” corresponding to particular patterns of muscle activations. Here, we do not make any such simplification; patterns of muscle activations are learnt by latent variables. Each muscle output was restricted to a binary activation. Below we present results for an arm with $C = 4$ compartments. The goal is to strike the target with any part of the arm. To direct exploration we provide a shaping reward at each time step: if the minimum distance between arm and target is decreased then a shaping reward of +1 is provided; if the distance is increased the reward is -1. The final reward for hitting the target is +50. An episode ends when the target is hit or after 300 steps.

We learned RBM-based policies with 32 stochastic hidden units, and an NN-based policy with 32 deterministic hidden units. We used energy-based features for (E)NATDAC as these are directly applicable in continuous-valued state spaces. Results for the octopus arm are shown in Fig. 3. The policy-gradient approaches performed significantly better in this experiment. In particular, the RBM trained by ENATDAC, and the NN trained by NATDAC, both learnt good policies that were consistently able to hit the target. Some ENATDAC runs were trapped in suboptimal maxima where the arm moves only in one direction, thus taking a longer time to reach the target on some episodes (see Figs. 5,6 in the supplemental material). The policies learned by EQNAC are slightly worse but the arm still learns to find and hit the target in the majority of cases. ESARSA performed relatively poorly. A video demonstration of the learnt octopus arm policies is available at: http://www.gatsby.ucl.ac.uk/~nheess/papers/ebrl/
5. Discussion

In our most challenging task, an energy-based policy was able to represent and learn, using ENATDAC, an effective control policy for a high-dimensional octopus arm. Unlike prior work, the latent variables automatically learnt to represent useful patterns of activations. In this task, a stochastic NN with deterministic hidden nodes was also able to solve the problem. This is not entirely unexpected as here a deterministic final policy is likely to be sufficient, while learning is simpler in the NN as it allows direct sampling of actions and the exact calculation of $\psi^\theta$ and $f(s)$. However, as demonstrated by the stochastic policy task, there are many domains in which partial observability, or an adversary, entails the need for highly structured stochastic policies that cannot be encoded by deterministic hidden nodes.

In our experiments the ESARSA algorithm did not achieve satisfactory results in the larger stochastic policy tasks, and also performed relatively poorly on the blocker and octopus arm tasks. The poor performance in some runs, and sensitivity to initial values, suggests that ESARSA is indeed suffering from divergence problems, presumably caused by the use of non-linear temporal-difference learning. In contrast, ENATDAC and EQNAC converged more robustly to a satisfactory solution in all tasks, suggesting that policy gradient algorithms may be more appropriate than value-based ones in this setting.

Our first algorithm, ENATDAC, is guaranteed to converge to a policy that achieves an average-reward that is close to local maximum. The algorithm requires the policy to be sampled many times: to select an action, to estimate the compatible features, and to construct the energy-based feature vector $f(s)$. However, we found empirically that a very small number of samples was sufficient to achieve good results: We used $K, L = 1$ in our experiments (cf. line 3 of Algorithm 1) except for the octopus arm where $K = L = 5$. Although the samples should be independent to ensure convergence, in practice the performance was unaltered by reusing the same samples.

Our second algorithm, EQNAC, uses a simple approximation to the advantage function. This algorithm does not require additional samples of the policy, beyond selecting the next action, making it more computationally efficient. It is also simpler than ENATDAC, using two parameter vectors rather than three. In practice, both algorithms performed well, achieving very similar performance on the blocker task, but with ENATDAC performing slightly better on the stochastic policy and more consistently on the octopus arm tasks.

In conclusion, reinforcement learning is particularly challenging in high-dimensional state and action spaces. Energy-based policies provide a promising architecture for addressing this challenge. We have demonstrated that prior work on value-based reinforcement learning, using the ESARSA algorithm, is often unsatisfactory when using highly non-linear policies such as an RBM. We have introduced two novel algorithms, based on energy-based policy gradient methods, that are more robust and effective than ESARSA. ENATDAC is guaranteed to converge to a near-local maximum in average reward; EQNAC is also robust in practice, and requires less computation. Both algorithms outperformed ESARSA on several high dimensional tasks.
